Machine Learning MIIS (lab 1)

(Due to October 26)

The goal of this task is to familiarize with the Colab environment and with scikit-learn, and to gain some experience on learning simple predictive models.

We will focus on the training error only and consider a training dataset, i.e., we will not look at generalization error on testing data.

Consider the LIBSVM repository of datasets: http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/

```
# # Example of downloading a dataset
# !wget -t inf https://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/binary/a1a
```

```
# # Example of loading a dataset
# from sklearn.datasets import load_svmlight_file
# X_train, y_train = load_svmlight_file("a1a")
# print(X_train)
```

1. Regression Task

Instructions

Choose a regression dataset and apply linear regression on a random subset of the training set of increasing size. You should select training sets that include more and more data points.

1.1. *Plot the approximation error (square loss) on the training set as a function of the number of samples* N *(i.e. data points in the training set).* [*You can use matplotlib for plotting. You can average curves over several permutations of the samples in the training dataset to obtain smoother curves, or even use errorbars.*]

1.2. *Plot the cpu-time as a function of* N.

1.3. *Explain in detail the behaviour of both curves and relate this behavior with what you would expect from theory.*

1.4. *Explore how the learned weights change as a function of N. Can you find an interpretation for the learned weights?* [*You can, for example, plot the value of each weight (in a different colour) as a function of N*].

Solution

We selected the Geographical Analysis Spatial Data (`space_ga`) regression dataset, which can be found here. It consists of just over 3 thousand examples reporting votes for the 1980 US presidential election, by county.

The dependent variable `VOTES` describes the number of votes cast.

The dataset includes the following 6 features:

- `POP` : no. people of voting age (18+)
- `EDUCATION` : no. people with 12th grade or higher education
- `HOUSES` : no. of owner-occupied houses
- `INCOME` : aggregate income
- `XCOORD` : X spatial coordinate of county
- `YCOORD` : Y spatial coordinate of county

```

1.3. Explain in detail the behaviour of both curves and relate this behavior with what you would expect from theory.

We ran linear regression on subsets of increasing sizes where each subset contains 500 more examples than the previous. We repeated this operation 50 times and averaged the results.

The first curve shows the average loss as a function of the number of training samples. As we can observe, the larger training set the lower the loss value. This behaviour is expected, since fitting a model on a larger training set allows us to obtain to better coefficients,

which in turn cause the model to generate more accurate predictions. Since the loss function computes the distance between the gold labels and model outputs, the more accurate the predictions are the lower the loss value will be. In this case, the decrease is steeper between subsets of 500 and 1,500 exmaples, after which the loss continues to decrease, albeit at a lower rate. However it should be noted that the numeric change in loss is actually very slight, only ranging betwee around .0234 to around .0233.

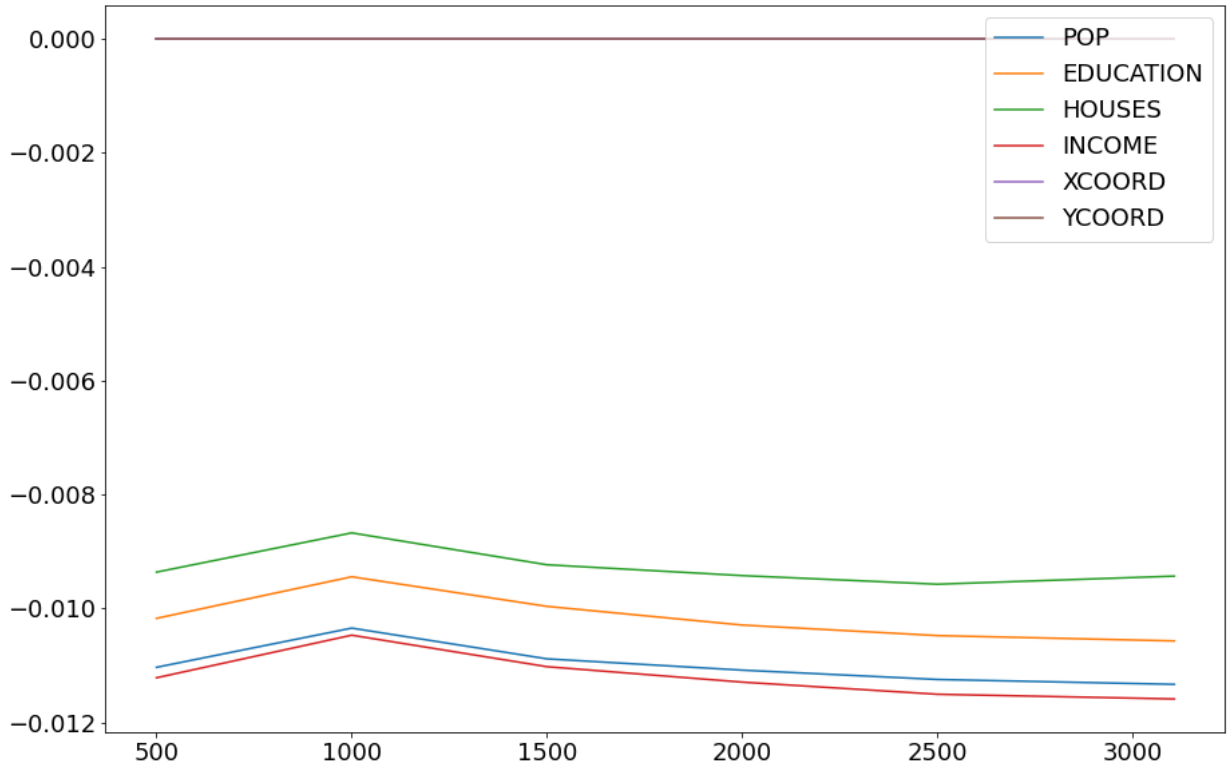
The second curve shows the average cpu time for model fitting as a function of the number of training samples. It can be observed that larger training sets correspond to longer cpu time. This is expected, because a larger training set contains more examples, and the model requires more calculations to fit the weights. More expensive computations trivially lead to an increased cpu time.

1.4. Explore how the learned weights change as a function of N. Can you find an interpretation for the learned weights?

[*You can, for example, plot the value of each weight (in a different colour) as a function of* N].

```
# Run linreg once
results = linreg(X, y, size_increment=500)
# Parse results into lists for plotting
sizes = []
coefs = []
for size,result in results.items():
  sizes.append(size)
  coefs.append(result["coef"])
```

```
# Plot coefs against N
plot = plt.plot(sizes, coefs)
labels = ["POP", "EDUCATION", "HOUSES", "INCOME", "XCOORD", "YCOORD"]
plt.legend(plot, labels, loc="upper right")
plt.show()
```



We ran linear regression on subsets of increasing size where each subset contains 500 more examples than the previous. Each line in the figure above shows how the corresponing weight changes when the training size grows, according to the top right legend.

We can observe that the weight associated with `YCOORD` does not significantly change with N, remaining close to $.00018$. This can be interpreted as a weak positive correlation with `VOTES`, corresponding to a $.00018$ (approx) increase in cast votes for every 1-unit increase in `YCOORD`. If we assume that `YCOORD` places the county on a point between two cardinal points on the US map, for example South vs North, then the higher the `YCOORD` the more North the county is located. Then, this correlation could be interpreted as decribing a tendency for Northern counties to cast slightly more votes.

The other weights are noticeably all negative, albeit very small. The changes for these are much more noticeable, and they all follow a similar pattern. Starting from a certain value, there is an increase between 500 and 1000 examples. Then all the weights slowly descend

until they reach a value that in most cases is lower than the one from the first model. In general, all of these can be interpreted as describing a slightly negative correlation with VOTES, i.e. a decrease in VOTES for every 1-unit increase wrt corresponding features.

2. Classification Task

Instructions

Choose a classification dataset and apply logistic regression. Repeat the previous steps using the mean accuracy instead of the squared loss.

2.1. *Plot the mean accuracy on the training set as a function of the number of samples N, i.e., data points in the training set.* [*You can use the scikit-learn implementation of* LogisticRegression*, but check carefully the default parameter values. Do not use regularization*].

2.2. *Plot the cpu-time as a function of N.*

2.3. *Explain in detail the behaviour of both curves and relate this behavior with what you would expect from theory.*

2.4. *Explore how the learned weights change as a function of N. Can you find an interpretation for the learned weights?*

Solution

We chose the German Credit Data dataset in its scaled numeric format (`german.numeric_scale`), which can be found here. It consists of 1,000 examples classifying people as good or bad credit risks using 24 features.

The dependent variable `y` describes whether the person is good or bad risk.

The original dataset contained 20 features, but some of its features were categorical. To obtain a numeric version of the dataset, some of these categorical features were turned into numeric indicators, for the purpose of making the dataset suitable for algorithms unable to use categorical variables.

We opted for the scaled version to favor convergence of our logistic regression model. The features were thus scaled to lie between -1 and 1.

Some examples of features:

- `AGE`
- `CREDIT_AMOUNT`

- `DURATION_CURR_EMPL`: duration (years) of current employment
- `DURATION_CURR_RES`: duration (years) of current residence
- `HOUSING_RENT`: if person rents the property they live in
- `HOUSING_OWN`: if person owns the property they live in
- `NO_CARDS` : no. of existing credits at this bank

```

2.3. Explain in detail the behaviour of both curves and relate this behavior with what you would expect from theory.

We ran logistic regression on subsets of increasing sizes where each subset contains 100 more examples than the previous. We repeated this operation 50 times and averaged the results.

The first curve describes the average accuracy as a function of the number of training samples. As we can observe, the accuracy is higher when the model is trained on larger subsets. With a subset of 100 examples we reach arount 73% accuracy, while with the whole

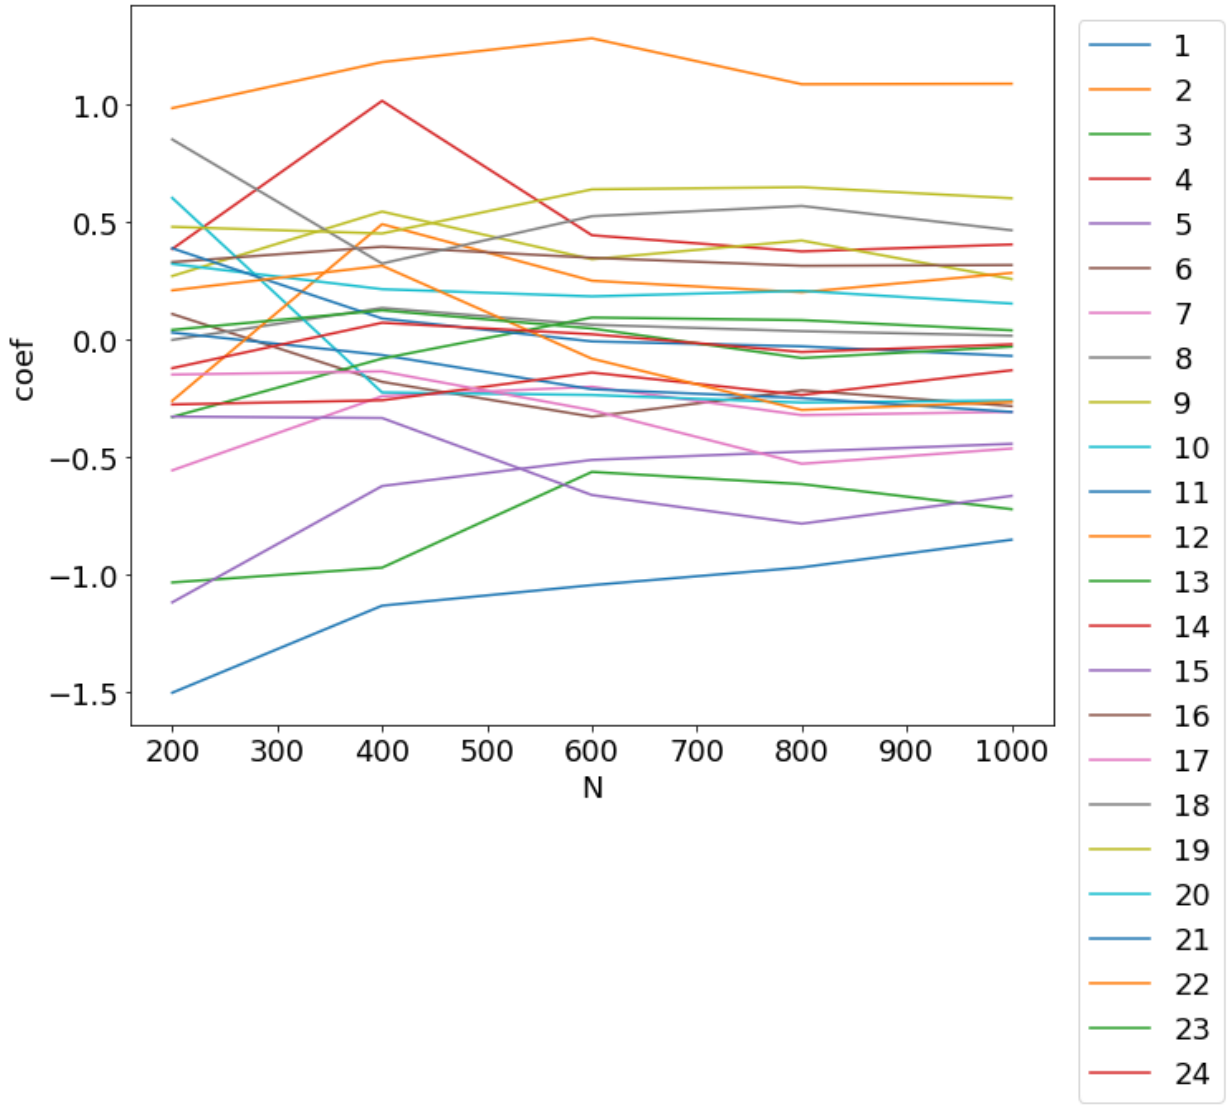
dataset we obtain around 78.6%. This improvement is expected, and due to the fact that the model is able to better fit weights when more data is provided. With better weights, predictions can be more accurate.

The second curve displays cpu time for model fitting as a function of the number of training samples. The plot shows a clear increase of cpu time required by the model for larger subsets. The growth is steep between sets of 100 and 400, after which we see a flat line up to subsets of around 500 examples, but this can be disregarded as most processes are subject to a certain degree of randomness in their scheduling. The growth then proceeds at a similar rate as before. As expected, more numerous calculations are required for subsets with more data points. Because of this, the cpu time is expected to be higher for larger datasets, and the behaviour described by our plot is consistent with this.

2.4. Explore how the learned weights change as a function of N. Can you find an interpretation for the learned weights?

```
# Run logreg once
results = logreg(X, y, size_increment=200)
# Parse results into lists for plotting
sizes = []
coefs = []
for size,result in results.items():
  sizes.append(size)
  coefs.append(result["coef"][0])
```

```
# Plot coefs against N
plot = plt.plot(sizes, coefs)
labels = range(1,25)
plt.legend(plot, labels, loc="upper right", bbox_to_anchor=(1.2, 1))
plt.xlabel("N")
plt.ylabel("coef")
plt.show()
```



Considering that there are numerous features, we increased the size step for each subset from 100 to 200, and ran logistic regression on 5 subsets instead of 10, so as to reduce the amount of points needed for plotting.

We can firstly observe that weights lie within a [-1.5,1.1] range. Moreover, we can see that for the first model 13 out of the 24 feature weights are positive while the rest are negative. For the last model, 11 feature weights are positive, and the other half are negative.

Out of the positive feature weights in the first model, weight 2 was the highest and remained high with increasing Ns. 11 and 16 became negative for the last model.

Out of the negative weights 7 and 15 decreased, while the rest all increased.

Unfortunately, details of how the numeric dataset was obtained are missing, so it is quite hard to interpret these weights because it is unclear what the feature they are associated with describe. However, in general the value of a weight represents the numeric change in the probability predicted by our model corresponding with a 1-unit increase wrt the feature associated, when all other features remain the same. For instance, let's assume that weight 19 is associated with `AGE`. Then, we have that this weight is equal to around .3 for the last model. Under this assumption, a for every year added to the age of the person, there is a 30% increase in the probability of predicting "good risk", keeping all other features fixed.
